Effect of salicylidene salicylhydrazide on testes of albino mice: A histomorphological study.

Shagufta Sultana¹, Muhammad Haris², Falak Naz³, Zainab Rehman⁴, Shazia Iftikhar⁵

ABSTRACT... Objectives: To evaluate salicylidene salicylhydrazide (SCS) for any possible toxicological effects on male reproductive system in Albino male BALB/c mice. Study Design: Experimental study. Study Setting: Department of Histopathology, Khyber Medical College Peshawar and Department of Pharmacy, University of Peshawar, Peshawar were utilized for conducting this study. Period: July, 2020 to December, 2020. Material & Methods: Male BALB/c mice were daily administered with SCS at 5, 25, and 50 mg/kg for 7 and 14 days. The body and testes weights were measured and the testes were subjected to histological tissue processing techniques. Results: The extent of testicular toxicity was evaluated by using modified Johnsen scoring system for assessing the level of spermatogenesis, and morphometric analysis by measuring the diameter of the seminiferous tubules, thickness of germinal epithelium, and area of interstitial cells of Leydig. The body and testes weights showed that the various doses of SCS have no substantial effects after 7 and 14 days. The tested doses of SCS did not produce any distinguishable change in the normal histological features of seminiferous tubules and interstitium after 7 days. However, after 14 days, the 50 mg/kg dose of SCS was associated with vacuolization and loosening of germinal epithelium. These mild-to-moderate histopathological aberrations was confirmed from morphometric analysis in this dose group in which a decrease in the seminiferous tubules’ diameter and reduction in the thickness of germinal epithelium along with an increase in the interstitial area were observed. Conclusion: These findings concluded that SCS is considered to be relatively safe.

Key words: Germinal Epithelium, Reproductive Toxicity Evaluation, Spermatogenesis, Testicular Toxicity Evaluation.

INTRODUCTION

The preclinical testicular toxicity evaluation of potential drug-like compounds is important and is a standard component of safety assessment during drug development process. Drugs as well as environmental pollutants have shown to greatly affect the spermatogenesis process during different stages of development in humans. These include cadmium, which severely affect the normal testicular function parameters including decrease testes weight, reproductive hormones, production of oxidative stress and induction of apoptosis in testes. Conducting toxicological studies on male reproductive system have received greater attention in recent years due to the increasing reports of reduction in the sperm counts along with other reproductive disorders including testicular cancer and possible transmission of exposure-related to the fetus. Various scientific techniques can be used to evaluate the male reproductive toxicity and this includes general systemic toxicity testing, assessing the functional effects on the reproductive organs of male, as well as mechanistic and molecular approaches conducted at the tissue level or in isolated cells. However, assessing the toxicological effect on the male reproductive system in humans is challenging as only a few clinical toxicological markers are available that can monitor possible alterations in testicular function including analysis of semen, testosterone and gonadotropin concentrations in the serum. Moreover, the real time monitoring of adverse
effects on testicular function in humans is also difficult due to the several months of latency period between the time of injury to the seminiferous tubules and the time of its clinical presentation and detection by semen analysis. There is also a dilemma of correlating the measurements of testicular function to changes and effects on male fertility.\(^1\)

Salicylidene salicylhydrazide is the derivative of salicylaldehyde benzoylhydrazone and synthesized by converting alkyl ester to hydrazide by refluxing with excess hydrazine hydrate and addition of aromatic aldehyde.\(^5\) It has a molecular weight of 256.26 g/mol and a melting point of 284-287 °C. It is observed that salicylidene salicylhydrazide has a strong cancer cell damaging potential as it strongly inhibited the growth of human colon adenocarcinoma cells. Its inhibitory anticancer potential (IC\(_{50}\)) is reported as 1.8, which is more potent than cisplatin (4.2) against these cancer cell lines.\(^5\) It also strongly inhibits synthesis of DNA in the rodent leukemia and hepatoma cancer cells, human bladder cancer, lung carcinoma and melanoma cells.\(^6\) Moreover, it also has β1 subunit containing GABA\(_A\) receptors inhibitory affinity and the interaction may involve an allosteric mechanism.\(^7\) Salicylidene salicylhydrazide has an analgesic potential that can be useful for treating peripheral neuropathic pain conditions linked with chemotherapy.\(^8\)

The present study evaluated salicylidene salicylhydrazide (SCS) for any possibility of producing toxicological effects on the male reproductive system, which may compromise its otherwise beneficial effectiveness in disease-state conditions.

**MATERIAL & METHODS**

The experiments were approved by the Ethical Committee of Khyber Medical College, Peshawar, Pakistan and approval for the study was granted vide registration number 42/PG/KMC. This was conducted at histopathology department, Khyber Medical College, from July 2020 to December 2020.

Male BALB/c mice weighing 20-40 g were included in the study. They were acclimatized in a light dark cycle of 12/12 h at 20-24°C. Salicylidene salicylhydrazide (97%) was obtained from Alfa Aesar, Thermo Fisher Scientific, Kandel, Germany. It was dissolved in a vehicle consisting of DMSO, Tween80 and normal saline in a ratio of 3:1:96.

The mice were divided into four main groups (A, B, C and D), while groups B, C and D were the experimental groups. Each group was further subdivided into two subgroups i.e. A1, A2, B1, B2, C1, C2, D1 and D2. Each subgroup comprised of 6 animals. Animals of each subgroup were kept in a separate cage. The subgroup A1 was the control group for B1, C1 and D1 experimental subgroups, while the subgroup A2 was the control group for experimental subgroups of B2, C2 and D2. Animals in the control subgroups A1 and A2 received the vehicle (3% DMSO, 1% Tween 80 and 96% normal saline) for 7 and 14 days, respectively. The animals in subgroups B1, C1 and D1 received SCS once daily through the intraperitoneal route at doses of 5 mg/kg, 25 mg/kg and 50 mg/kg, respectively for consecutive 7 days. Likewise, SCS was intraperitoneally administered to animals in subgroups B2 at 5 mg/kg, C2 at 25 mg/kg and D2 at 50 mg/kg for consecutive 14 days. The experimental plan is shown in Table-I.

**Table-I. Experimental plan.**

At the end of 7 and 14 days, the animals were sacrificed and their testes were surgically
removed. The testes were weighted along with epididymis. They were then placed in labeled jars containing 10% neutral buffered formaldehyde. After 48 hours, the tissues were dehydrated in graded ethanol solutions (70-100%), each for 1 h. The tissues were then cleared in alcohol-xylene solution and then in 100% xylene with two changes each for 1 h at 45-47°C under constant stirring. The tissues were then infiltrated with paraffin wax and were then embedded. The embedded tissues were sectioned through a rotary microtome at 4-5 micron and were then stained with hematoxylin and eosin and periodic acid-Schiff for microscopic evaluation.9-11

The tissue slides were examined under a light microscope for various parameters including degeneration of germ cells, multinucleate aggregation, depletion of germ cells, exfoliation of germ cells, vacuolization of the germinal epithelium of the seminiferous tubules, contraction of tubules, dilatation of tubules, retention of spermatids, necrosis of the seminiferous tubules, atrophy, hypertrophy, hyperplasia and adenoma of Leydig’s cell and disorganization of the tubular contents. The histopathological changes occurring in the testes were examined under a 400x original magnification using a trinocular microscope. The level of spermatogenesis was evaluated using the modified Johnsen scoring system.12

The morphometric analysis was performed for the measurement of seminiferous tubular diameter, germinal epithelium thickness, and area of interstitial cells of Leydig under high power field. These measurements were conducted using the Nikon microscope (ECLIPSE Ci-L) with a standalone camera control unit (DS-L3).

The histopathological changes were evaluated by an experienced pathologist who was blinded to the various treatment groups. The quantitative data were expressed as mean ± standard deviation (SD) or standard error of the mean (SEM). Statistical analyses were carried out using one-way ANOVA or two-way repeated measures ANOVA followed by appropriate post hoc tests. A P value less than 0.05 was accepted as statistically significant.

RESULTS
After 7 days, the group of mice treated with the vehicle (A1) showed a normal gross behavioral profile. The mice in the subgroups administered with the tested doses of SCS at 5, 25 and 50 mg/kg (groups B1, C1 and D1) were also observed to perform their normal general activity. Moreover, no aggressive behaviors were observed during the 7 days of observation.

After 14 days, the group of mice treated with the vehicle (A2) exhibited a normal behavioral and locomotor profile. The animals that were administered with the 5, 25 and 50 mg/kg doses of SCS (groups B2, C2 and D2) were also grossly observed after dosing in their respective cages. It was found that these doses have no gross effect on the behavior as well as on the locomotion.

Effect of salicylidene salicylhydrazide on body weight
After 7 days of consecutive treatment with SCS, the animals in the various groups did not show any statistically significant change in the body weight as no significant difference was observed in the groups of mice administered with SCS at the tested doses of 5, 25 and 50 mg/kg (groups B1, C1 and D1) as compared to the vehicle treated group (group A1). Similarly, administration of SCS for 14 days has no significant effect on the body weight of animals allocated to the various treated groups (groups B2, C2 and D2) (Figures-1A and 1B).

The different groups of animals administered with the tested doses of SCS at 5, 25 and 25 mg/kg (groups B1, C1 and D1) have shown no significant alterations, when their diameters were measured as compared to the vehicle treated control animals’ group (group A1) after 7 days. After 14 days, the groups of animals administered with SCS at 5, 25 and 50 mg/kg (groups B2, C2 and D2) showed a non-significant decrease in their seminiferous tubules diameter when compared to that of the vehicle treated animals’ group (Figures-6A and 6B).
Figure-1. Effect of salicylidene salicylhydrazide (SCS) at 5, 25, and 50 mg/kg on body weight (A and B) and relative testes weight (C and D) after 7 and 14 days of administration. Each column represents mean body weight or relative testes weight in grams (g) or milligrams (mg) ± SEM. SCS groups were compared with the vehicle groups. No significant difference was observed, two-way repeated measures ANOVA followed by Dunnett’s post hoc test, n = 6 mice per group.

Figure-2. Representative photomicrographs (H&E, 400x) of the germinal epithelium of seminiferous tubules from testes of mice after 7 days of treatment with vehicle (A) showing normal histology of dark and pale spermatogonia (arrow heads), numerous pachytene spermatocytes (small arrows), rounded and elongated spermatids (large arrows) with their tails protruding into the lumen (asterisk), and Leydig cells (white arrow) in the interstitial compartment. Normal histological features of the germinal epithelium were observed in the testes of mice treated with SCS at 5 mg/kg (B), 25 mg/kg (C), and at 50 mg/kg (D).

Figure-3. Representative photomicrographs (PAS, 400x) of a section of germinal epithelium from the testes of mice after 7 days of administration with the vehicle (A) showing the normal histology of interstitial cells of Leydig (large white arrow), pale and dark spermatogonia (arrow heads), primary spermatocytes (small arrows), numerous rounded spermatids (large arrow) with tails of elongated spermatids (large arrow) appeared protruding into the lumen and Sertoli cell (small white arrow). Normal histology of germinal epithelium lining the seminiferous tubules was observed in the group of mice treated with SCS at 5 mg/kg (B), 25 mg/kg (C), and 50 mg/kg (D).

Figure-4. Representative photomicrographs (H&E, 400x) of the germinal epithelium of seminiferous tubules from testes of mice after 14 days of treatment with vehicle (A) showing normal histological appearance of spermatogonia (small arrows), pachytene spermatocytes (arrow heads), rounded spermatids (large arrow) as well as elongated spermatids (large arrow) with their tails extending into the luminal space (asterisk) and numerous interstitial cells of Leydig (white arrow). Normal histology of the germinal epithelium cells lining the seminiferous tubules was observed in the testes of mice treated with SCS at 5 mg/kg (B), 25 mg/kg (C), and 50 mg/kg (D). The major histopathological finding in the 50 mg/kg treated group (D) was the epithelial vacuolization as revealed from the numerous vacuoles (arrow heads) that are visible in the germinal epithelium.
The groups of animals administered with the tested doses of SCS at 5, 25 and 50 mg/kg (groups B1, C1 and D1) showed no significant changes in the height of the germinal epithelium lining the seminiferous tubules. The groups of animals administered with SCS at 5, 25 and 50 mg/kg (groups B2, C2 and D2) showed a non-significant dose-dependent reduction in the height of germinal epithelium, with a prominent decrease was noted with the higher dose treated group (Figure-6C and 6D).

After 7 days, the groups of animals administered with SCS at 5, 25 and 50 mg/kg (groups B1, C1 and D1) showed no apparent change in the area among the seminiferous tubules in addition to a slight increase for the 50 mg/kg treated animals group, as compared to the vehicle treated animals control group (group A1). After 14 days, the groups of animals treated with SCS at 5, 25 and 50 mg/kg (groups B2, C2 and D2) produced a non-significant dose-dependent increase in the area of the interstitial space among the seminiferous tubules when compared to the vehicle treated group (group A2) (Figures-7A and 7B).
The groups of mice treated with SCS at 5, 25 and 50 mg/kg (groups B1, C1 and D1) showed no remarkable changes in the Johnsen scores as compared to the scores obtained for the vehicle administered group (group A1) after 7 days. After 14 days of treatment, the groups of animals treated with SCS at 5, 25 and 50 mg/kg (groups B2, C2 and D2) showed a non-significant dose-dependent reduction in the scores of the spermatogenesis with a prominent decrease in the level of spermatogenesis was noted for the 50 mg/kg dose group (Figures-7C and 7D).

The testicular toxicity evaluation of mice treated with the different doses of SCS was compared with respect to the experimental time-periods of day 7 and day 14. No significant toxicological changes in the seminiferous tubules were observed on day 7 among the different treated groups. After 14 days, a variation in the testicular toxicity was noted. There was a slight increase in the toxicity for the 5 mg/kg group, while a prominent increase in toxicity was observed for the groups of SCS treated mice at 25 and 50 mg/kg doses (Figure-8A).

The testicular toxicity observed in the treated mice after day 7 and day 14 was compared with respective to the different doses of SCS i.e. 5, 25 and 25 mg/kg. The SCS treated group at 5 mg/kg has no differences in testicular changes between the tested days. For the 25 mg/kg dose, a slight increase in the toxicity was observed on day 14 as compared to day 7. The higher tested dose of 50 mg/kg showed a marked toxicological change on day 14 in comparison to changes observed on day 7 of the experiment (Figure-8B).

DISCUSSION
In the present study, salicylidene salicylhydrazide was assessed for its toxicological propensity in mice. The testicular tissue was evaluated for any morphological alterations occurring after repeated administration for 7 and 14 days. It was observed that the 14 days treatment with the 50 mg/kg dose produced histopathological changes in the seminiferous tubules.

Exposure to the antimicrobial agent, mequindox at 55 and 110 mg/kg doses produce necrosis of the seminiferous tubules that is associated with germinal epithelium exfoliation, arresting of spermatogenesis, atrophy and disappearance of spermatogenic cells. The ingestion of doxorubicin at 7.5 mg/kg is associated with atrophy of spermatogenic cells and atrophy of germinal epithelium.
of the seminiferous tubules along with a loss of spermatogenic cells. It also causes vacuolization of the germinal epithelium containing multinuclear giant cells and other degenerative changes. In addition, there is also edematous changes in the interstitial tissue with a loss of interstitial cells of Leydig. The degenerative changes induced by the administration of adriamycin at a dose of 10 mg/kg include reduction in the size of the germinal epithelium, formation of giant cells and thickening of the basal layer of the seminiferous tubules. The administration of methotrexate group at 20 mg/kg is associated with a loss of spermatogenic cells and Sertoli supporting cells from the germinal epithelium along with vacuole formation, inflammatory changes in the interstitial space and degeneration of interstitial cells of Leydig. Similarly, cisplatin administration at 3 mg/kg is also associated with loss of spermatogenic cells and Sertoli cells.

In this study, the potential toxic nature of salicylidene salicylhydrazide was observed by measuring the diameter of the seminiferous tubules, thickness of the germinal epithelium and area of the Leydig interstitial cells in the different tested group. Although the low-dose and short duration (for both low and high doses) were observed to be safe with regard to the testicular histopathological changes; however, the 14 days treatment with the 50 mg/kg dose was found to have an effect on these morphometric parameters in the testicular tissue. The administration of quinine is shown to produce a gradual decline in the diameter of the seminiferous tubules after chronic dosing along with an increase in the volume of connective tissue stroma in the interstitium. Chronic exposure to malathion is associated with a decrease in the germinal epithelium thickness, luminal, and tubular diameter of the seminiferous tubules. Cisplatin has been shown to produce significant a decrease in the seminiferous tubules diameter and an increase in the lumen diameter of tubules. A significant decrease in the volume of the seminiferous tubules and an increase in the volume of the interstitium have been observed after administration of cocaine and caffeine. Administration of ribavirin also produce a decrease in the seminiferous tubular diameter and epithelial height of the seminiferous tubules. Moreover, dexamethasone administration has also shown to be associated with a decrease in the seminiferous tubules diameter and a reduction in the height of seminiferous germinal epithelium. Administration of cannabis extract at doses of 40, 60 and 80 mg/kg have detrimental effect on the testis as revealed from the significant decrease in the seminiferous tubules diameter along with shrinkage of tubules. The selenium treated animals at a dose of 8 ppm has a considerable effect on the testicular tissue as revealed from the decrease in the diameter of the seminiferous tubules, reduction in the height of the germinal epithelium and number of spermatogenic cells. Likewise, ingestion of fluoride was also associated with a decrease in the epithelial height and tubular diameter of testis.

In this study, any testicular toxicity associated with the administration of salicylidene salicylhydrazide was investigated using modified Johnsen scoring system, which evaluates the level of spermatogenesis. The 50 mg/kg treated group was observed to produce aberrations in the spermatogenesis process after 14 days of treatment. Exposure to chemicals and drugs have been shown to produce changes in the Johnsen scoring system that are suggestive of alterations in the spermatogenesis process. The anticancer drug, cisplatin also has a toxicological propensity for the seminiferous tubules and associated with a significant decrease in the Johnsen’s scores. The Johnsen’s tubular biopsy score for the groups of animals treated with doxorubicin was significantly lowered than the control groups animals and an increase in the tubular scoring was observed after the doxorubicin animals were given a combination of zinc and alogliptin. Application of the Johnsen’s testicular biopsy scoring system to the seminiferous tubules of testes from the sildenafil, tadalafil and tramadol administered animals revealed a significant decrease in comparison to the control group after chronic administration with high doses of phosphodiesterase-5 inhibitors and tramadol. Similarly, the Johnsen’s testicular biopsy scores were also employed to validate the underlying histopathological changes occurring in the
testicular tissues in the studies conducted on cadmium,\textsuperscript{2} methyl parathion\textsuperscript{30} and a significant decrease was noted in the scores after administration of these agents.

These prospective controlled studies should look in-depth for the effect of salicylidene salicylhydrazide on complete semen analysis, serum concentrations of reproductive hormones including testosterone, analysis of testicular glucose, lactate and lactate dehydrogenase, assay of testicular enzymatic and non-enzymatic antioxidants and checking for markers of apoptosis in the testes. In addition, specific staining procedures for cellular apoptosis along with electron and confocal microscopic ultrastructural techniques can also be utilized.

**CONCLUSION**

From these findings, it can be concluded that salicylidene salicylhydrazide is considered to be relatively safe. However, its absolute safety can only be established if further thorough studies are designed.
